Fossiliferous limestone with forams

fossiliferous limestone containing visible shell and skeletal fragments.

Characteristics: Fossiliferous limestone with forams is a sedimentary rock, made from the shells of tiny sea creatures called foraminifera. Over long periods, these shells mix with bits of coral and algae on the ocean floor. Slowly, the layers get compacted and cemented, forming limestone packed with fossils that tell the story of life in ancient oceans.

Natural occurrences: Fossiliferous limestone with forams occurs mainly in shallow, warm marine settings where foraminifera thrived. Deposits are common on continental shelves, carbonate platforms, and reef environments. They are formed from accumulation and lithification of calcareous shells and
skeletons. It captures past ocean life through the fossils of marine organisms that once lived there. Major occurrences are found worldwide, including the Mediterranean, India, USA, and Australia.

Fun facts: It is used in lime production, glass making, and as a flux in steel manufacturing.
They also provide valuable data for oil and gas exploration by indicating past marine environments**.**
